

# **The QBO in 110L WACCM: the importance of vertical resolution**

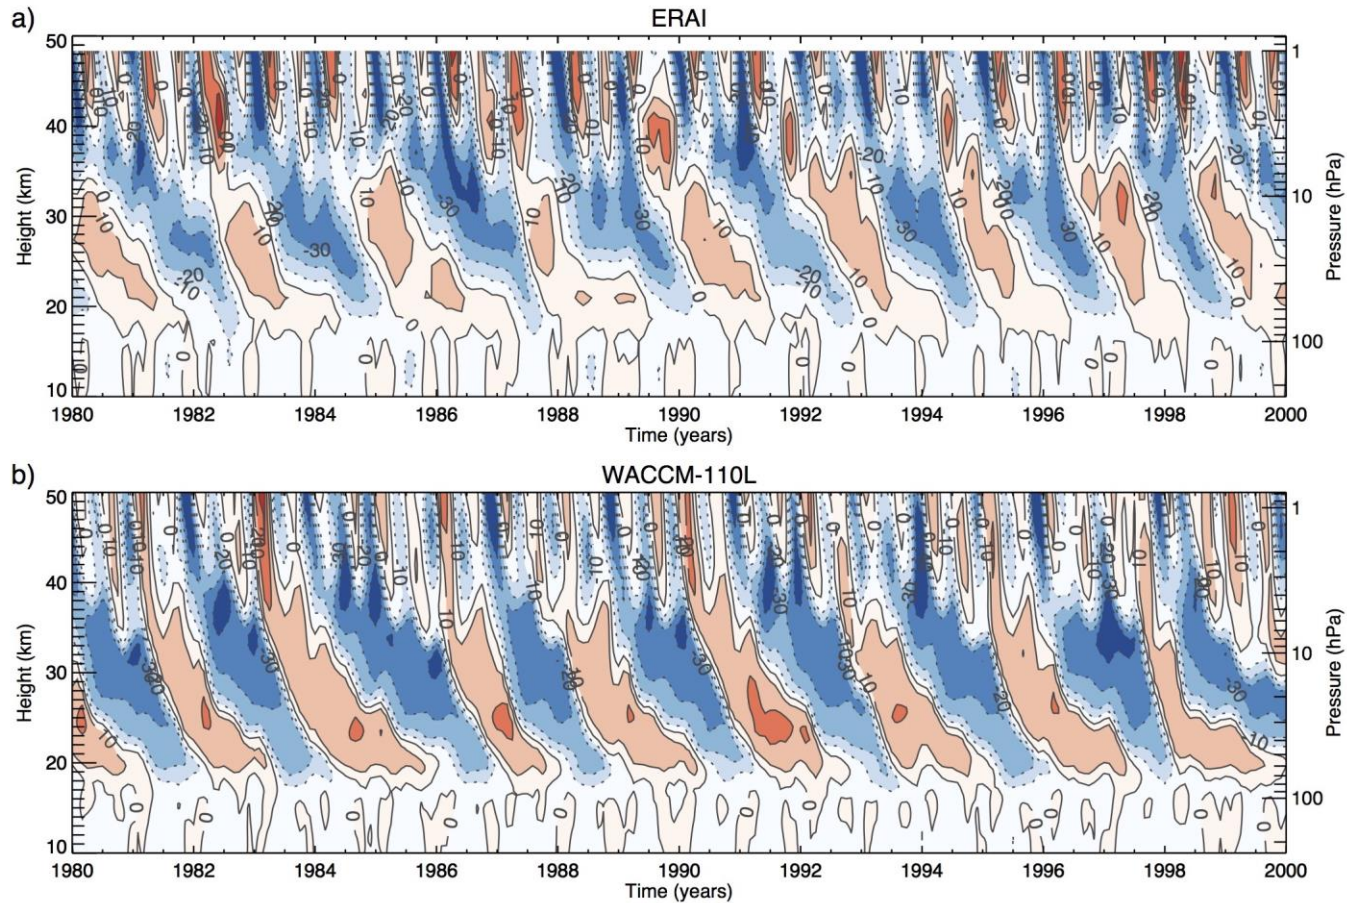

Rolando Garcia and Yaga Richter  
National Center for Atmospheric Research  
Boulder, CO

# high-vertical resolution version of WACCM5.4

- QBO simulations for the period 1980-2010 using a modified version of **WACCM-5.4** (1° horizontal resolution, similar physics as WACCM6)
- tropical GW are parameterized with the Beres convective GW scheme (Beres et al., *JAS*, 2005) (GW excitation dependent on convective heating)
- the 110L model has much higher resolution than the standard, 70L WACCM from the top of the boundary layer through the middle stratosphere

# $U_{eq}(t)$ : WACCM vs. ERA-Interim data

- 110L WACCM reproduces a QBO in very good agreement with observations in most respects
- Observed period ~ 28 months (1952-2016); simulated period = 27.5 months (1980-2010)
- Amplitude slightly too strong compared to observations

# QBO structure from Coh<sup>2</sup> analysis

(a) WACCM

Amp, Phi: (0.050, 0.025) cpm 1980–2010

sig: 95%, bp: (-0.5°, 14.1 hPa),

(b) ERA-Interim

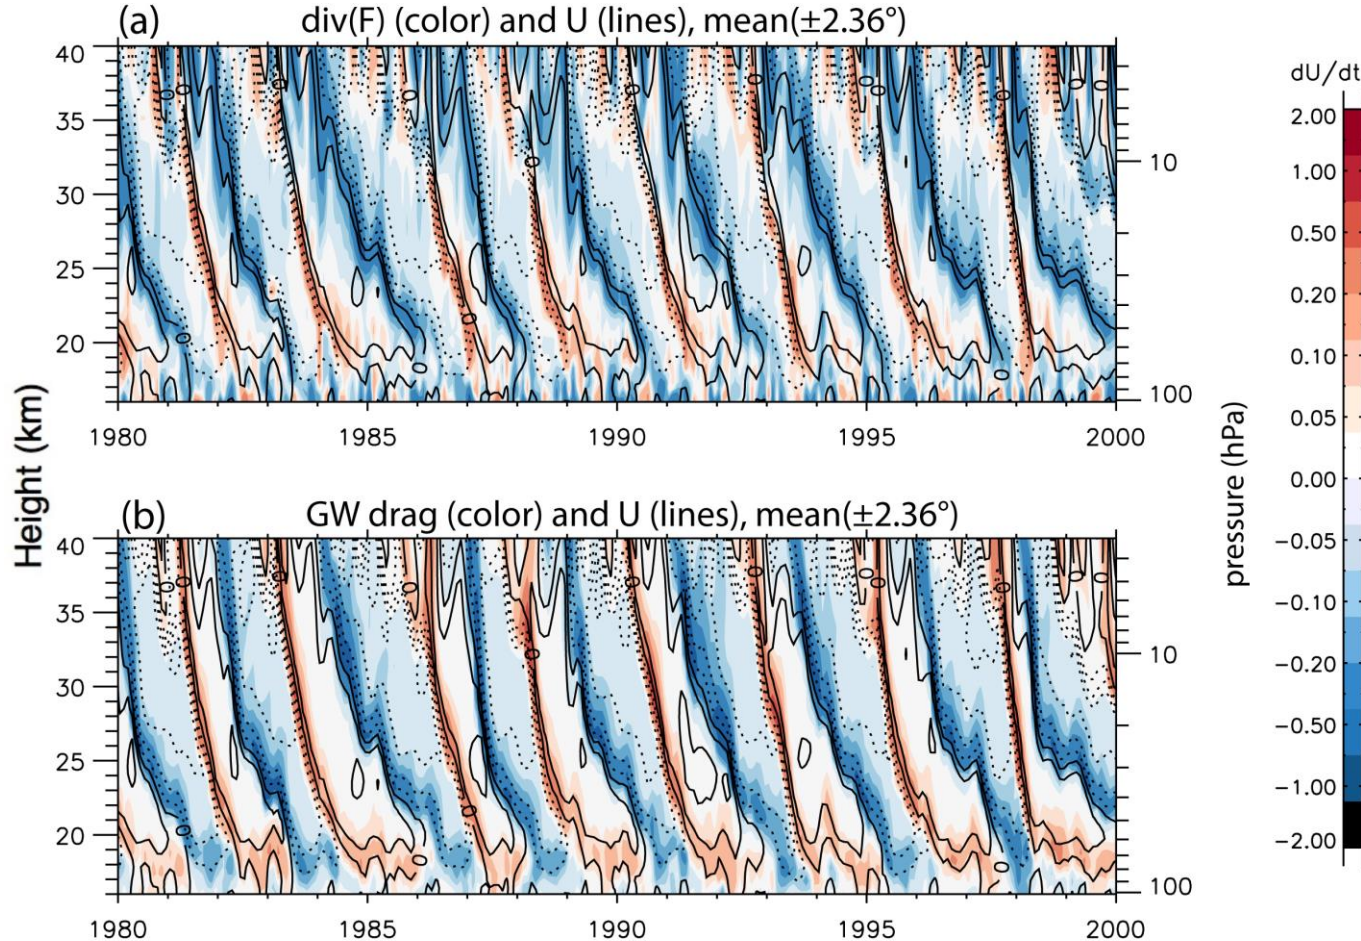

Amp, Phi: (0.050, 0.025) cpm 1980–2010

sig: 95%, bp: (0.0°, 15.2 hPa),

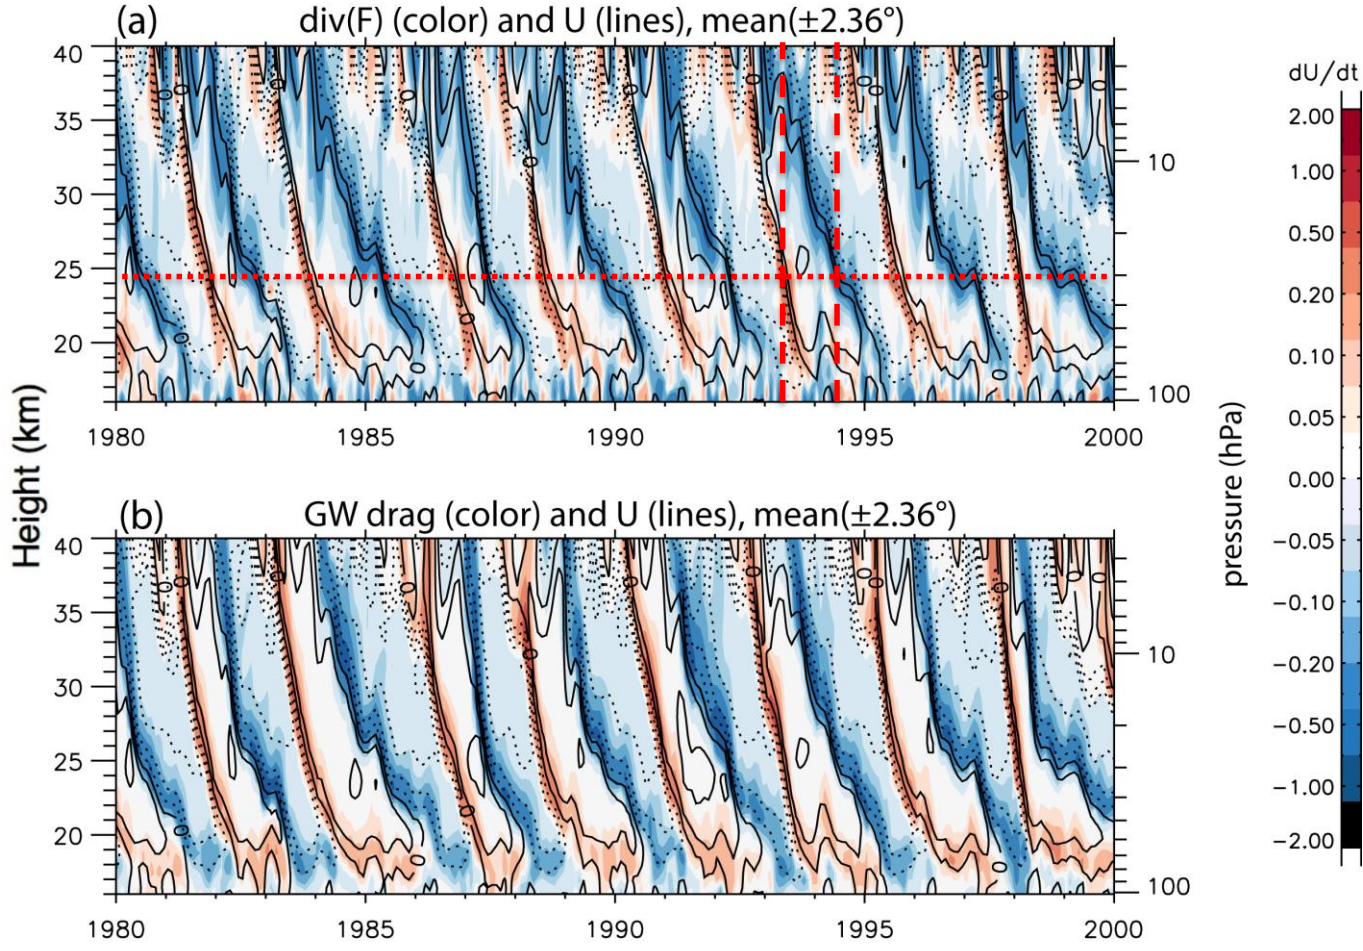

- Coh<sup>2</sup> analysis provides a “compact” view of the QBO
- amplitude somewhat too strong
- phase behavior in close agreement with ERA-I

# div( $\mathbf{F}$ ) and GW drag (color) vs. $U_{eq}(t,z)$ (contours)

- parameterized  $div(\mathbf{F})$  and GW drag ( $\pm 5^\circ$  averages) contribute comparably to E and W phases
- easterly and westerly forcing are concentrated along the respective vertical shear zones
- accelerations are of order  $1 \text{ m s}^{-1} \text{ day}^{-1}$
- Next: look in detail at  $div(\mathbf{F})$  due to explicitly resolved waves

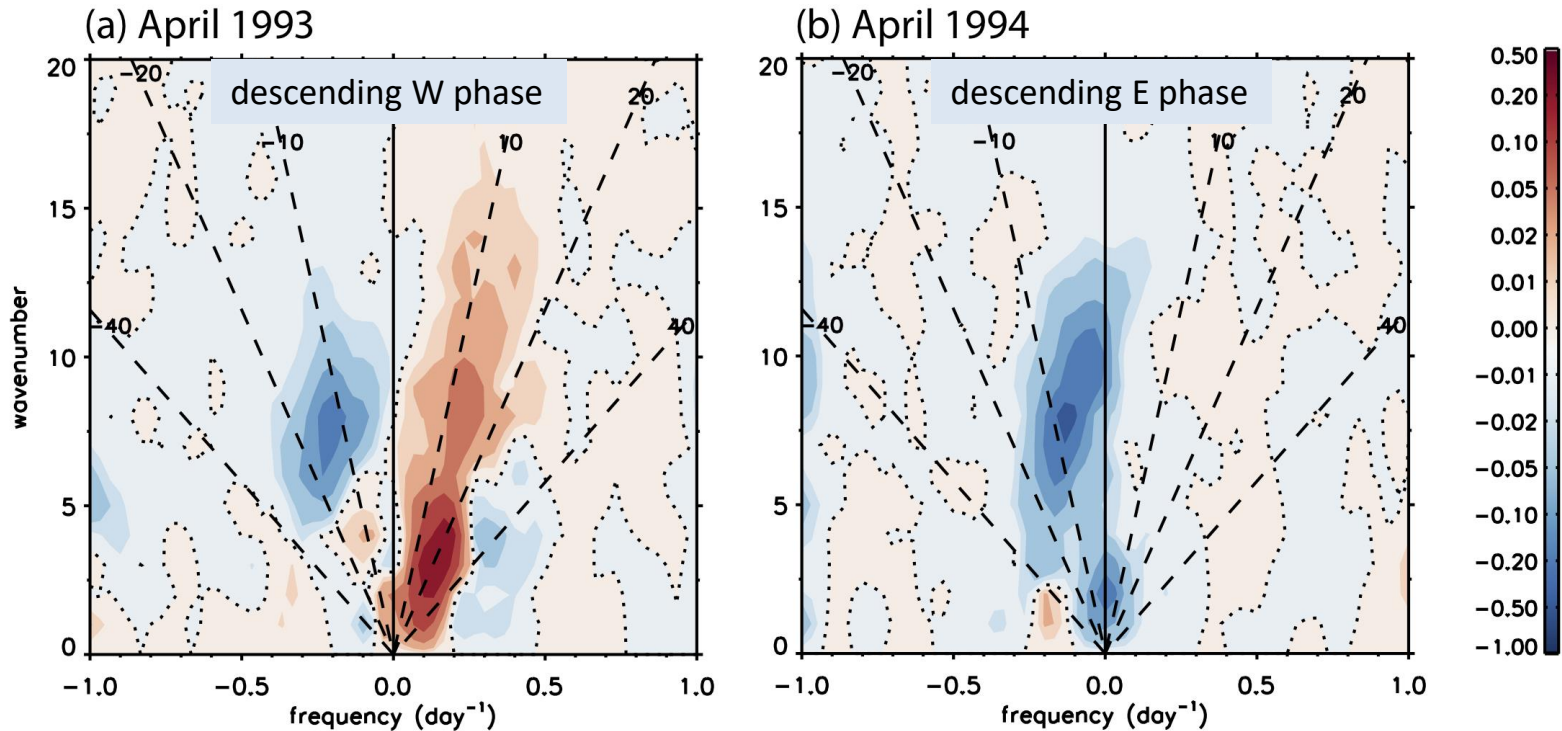

# div(F) and GW drag (color) vs. $U_{eq}(t,z)$ (contours)

- look in detail at div(F) due to explicitly resolved waves in E and W phase

# div(**F**) spectrum ( $\pm 5^\circ$ ), W and E phase

div(**F**) spectral density ( $\text{ms}^{-1}\text{day}^{-1} / \text{day}^{-1}\text{wno}^{-1}$ )  
27 km (22 hPa); mean  $\pm 5.2^\circ$

- eastward div(**F**) strongest for  $k = 1-4$  (but extends to  $k > 15$ ), present *only during W phase*
- westward div(**F**) strongest at  $k = 5-10$ , centered on  $k \sim 7-8$ , present *in both W and E phases*

# div(F) of eastward waves

- strongest along Equator, during descending W phase
- uniformly weak at other times (not shown)
- consistent with expected forcing by *Kelvin waves*

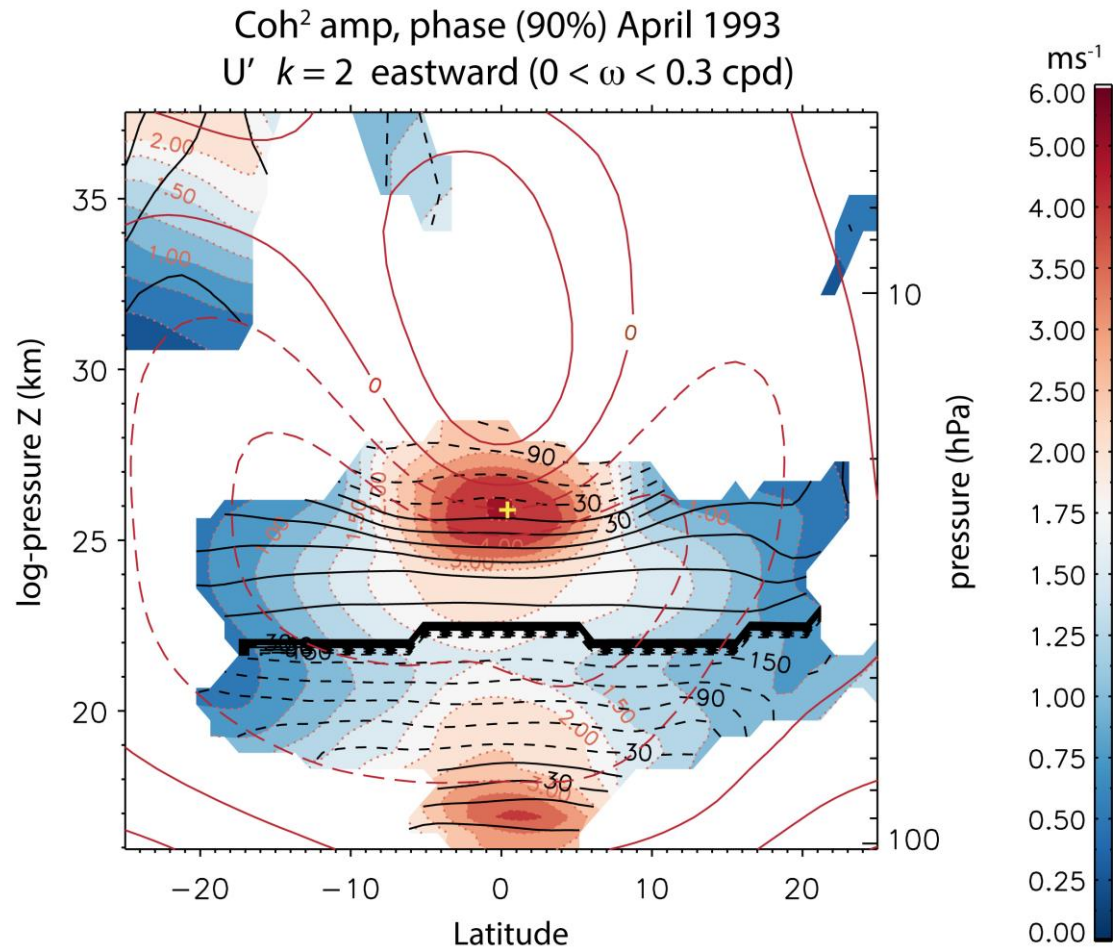

April 1993: descending W phase at 25 km

# eastward wave structure

- structure via  $\text{Coh}^2$  analysis (eastward frequencies; base point: cross)
- present in W phase only
- largest amplitudes at planetary scales ( $k = 1-4$ ); example shown is  $k=2$
- $u' \gg v'$  (only  $u'$  shown here)
- Kelvin wave structure (similar structures found at other  $k$ )
- *consistent with expectations* for  $\text{div}(\mathbf{F})$  in the W phase of the QBO

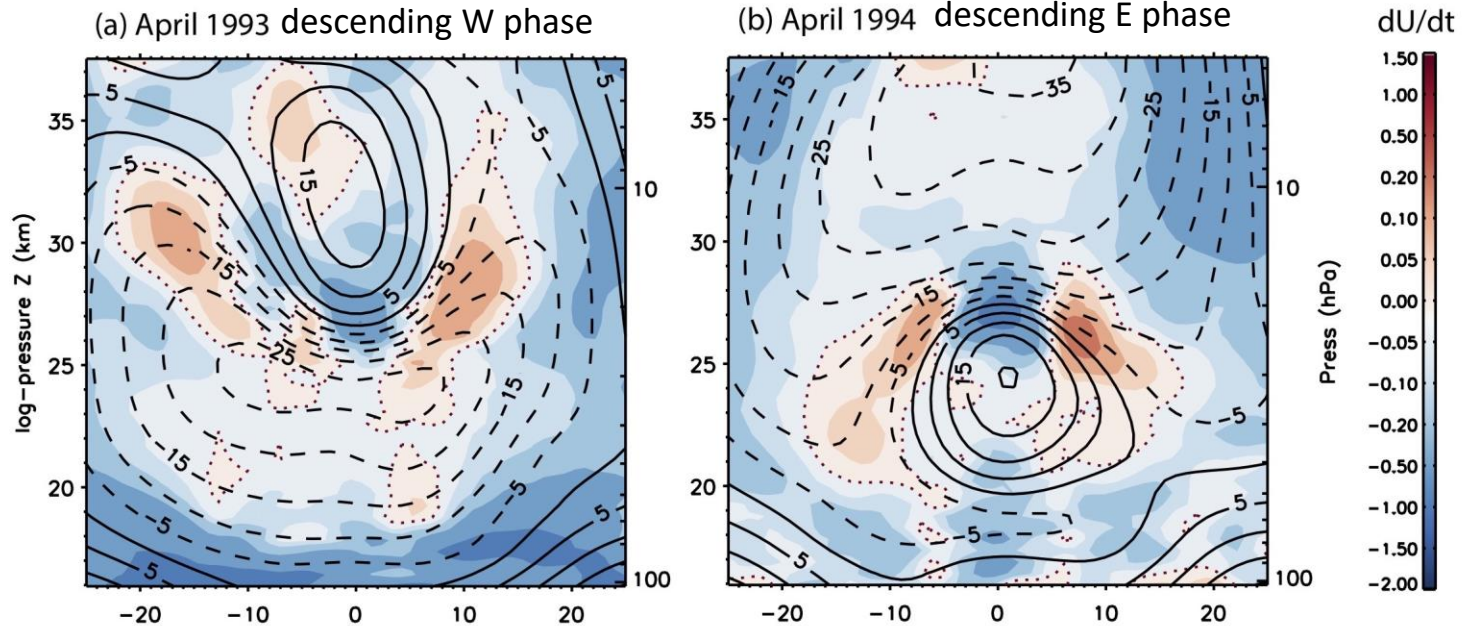

# eastward waves: lowermost stratosphere

- structure via  $\text{Coh}^2$  analysis (eastward frequencies; base point: cross). Note reduced vertical domain.
- in this example, the W jet is approaching the tropopause
- this  $k = 2$  Kelvin wave has low frequency, narrow horizontal scale and short vertical wavelength
- $\lambda_z \sim 6 \text{ km} \rightarrow$  need for high vertical resolution to represent properly

# div(**F**) of westward waves

div(**F**) due to westward waves ( $\text{ms}^{-1}\text{day}^{-1}$ )

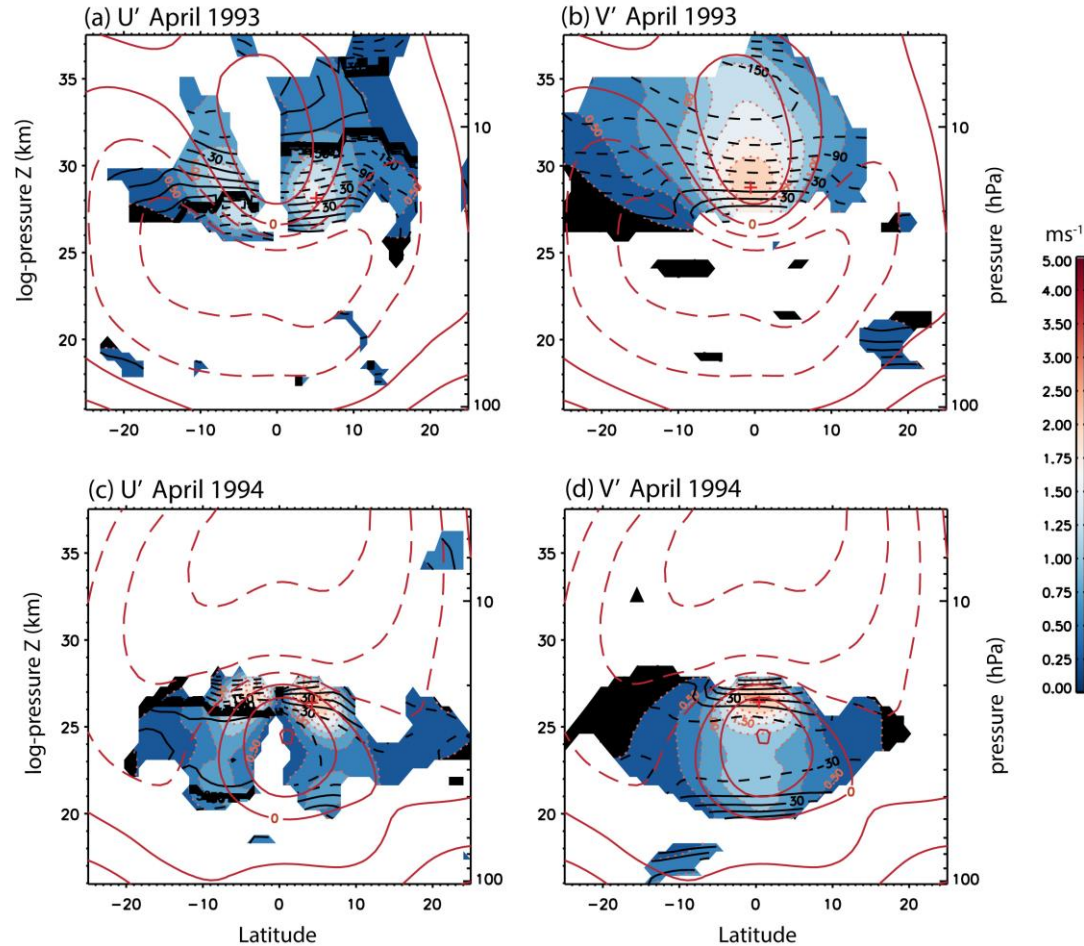

- present during both descending W phase and descending E phase
- characteristic pattern of alternating sign, with negative acceleration near the Equator and positive on either flank

# westward wave structure

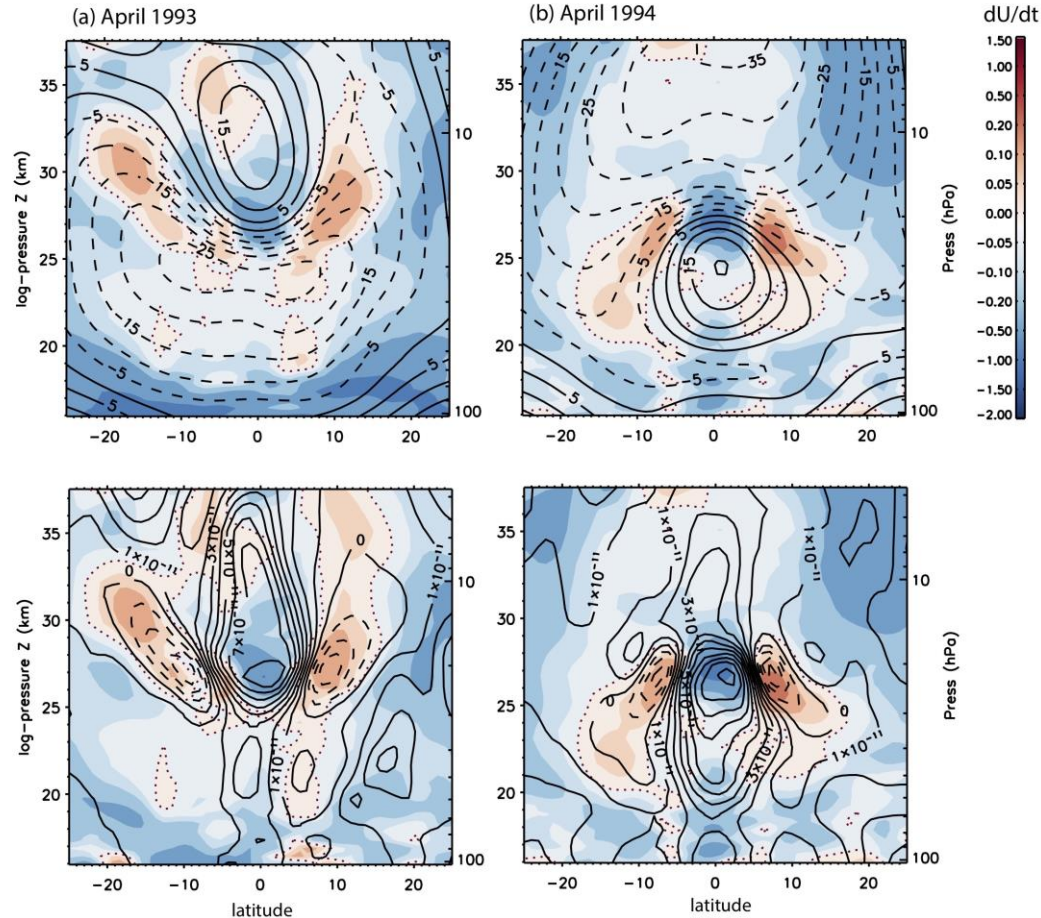

Coh<sup>2</sup> amp, phase (90%)  
 $k = 8$  westward ( $-0.3 < \omega < 0$  cpd)

- structure via Coh<sup>2</sup> analysis (westward frequencies; base point: cross).
- $u'$  and  $v'$  (shown in this example for  $k = 8$ ) are of comparable magnitude
- structure is consistent with RG waves; note very short vertical wavelength,  $\lambda_z \sim 4\text{-}5$  km  $\rightarrow$  need high vertical resolution
- waves are confined to the vicinity of the “nose” if the QBO westerly jet
- turns out these waves are generated locally due to barotropic instability of the (bottom or top side) of the QBO westerly jet (cf. Hamilton, 1984, 2001; Shuckburgh et al., 2001). *This is a new (unexpected) finding* in the context of QBO modeling

# barotropic instability

div( $\mathbf{F}$ ) due to westward waves ( $\text{ms}^{-1}\text{day}^{-1}$ )

- $\text{div}(\mathbf{F})$  with contours of zonal-mean zonal wind  $U$  superimposed (top row)
- $\text{div}(\mathbf{F})$  with barotropic vorticity gradient  $\zeta_y = \beta - U_{yy}$  superimposed in bottom row
- $\zeta_y$  meets the necessary condition for barotropic instability (gradient reversal)

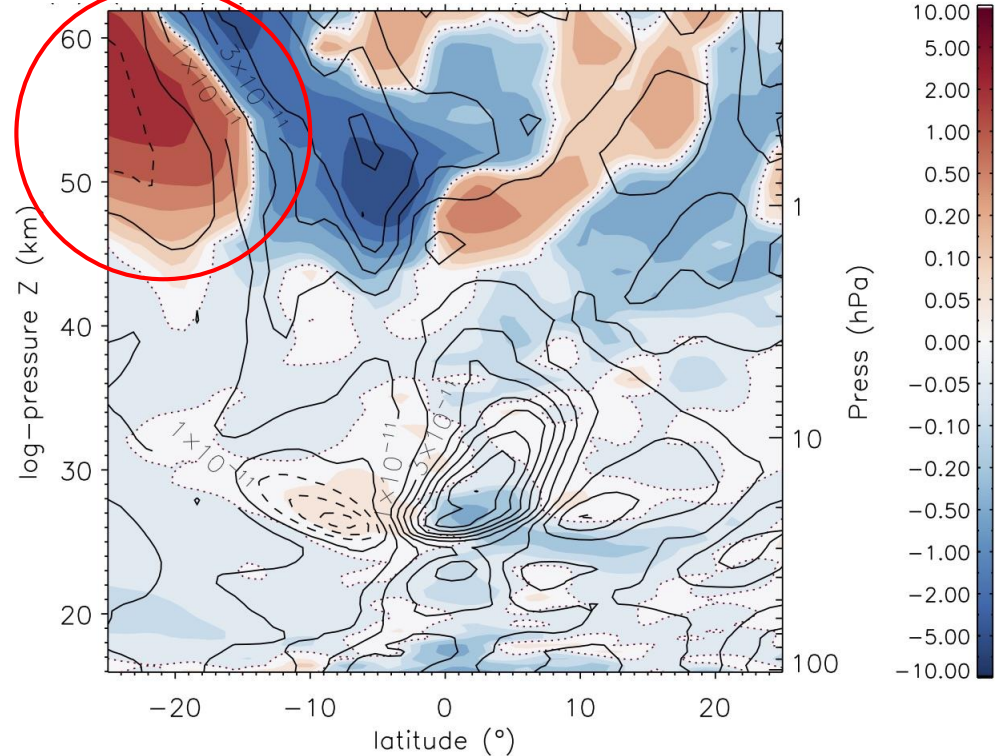

# upper stratosphere (SAO W phase)

div(**F**) with U contours superimposed

con

div(**F**) with  $Z_y$  contours superimposed

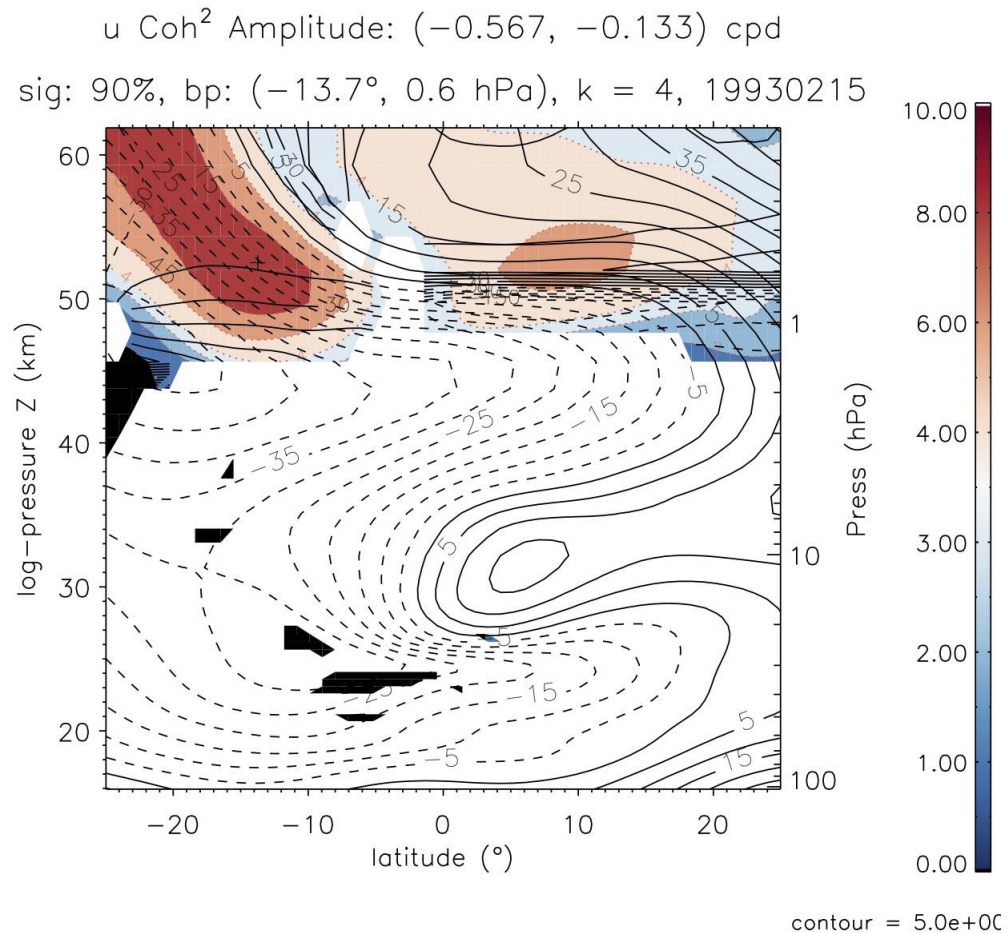

contour = 1.0e-11

- $\text{div}(\mathbf{F})$  pattern associated with SAO W phase (Feb-Mar) alternates in sign with latitude
- $\zeta_y$  meets the necessary condition for instability off Equator
- broader patterns than found in QBO region: how might this depend on vertical resolution?

# wave structure in the upper stratosphere

- structure for  $u'$  at  $k = 4$  westward (largest amplitude found in spectral analysis—not shown)
- broad structure suggestive of RG or Rossby waves
- how would finer vertical resolution impact this result?

# Summary

- high-vertical resolution 110L WACCM generates a realistic QBO
- $\text{div}(\mathbf{F})$  in descending W phase is due mainly to large-scale ( $k = 1-4$ ) Kelvin waves
- $\text{div}(\mathbf{F})$  in descending E phase due to smaller-scale ( $k > 5$ ) RG waves, apparently excited *in situ* by barotropic instability
- other, apparently unstable waves are present in connection with the W phase of the SAO at the stratopause—how are these impacted by coarser vertical resolution at that altitude?
- → high resolution WACCM simulations allow studies of previously inaccessible features of tropical dynamics

more details: Garcia and Richter, *JAS* (January 2019)
